Abstract:

As technological progress is made in electronic manufacturing, navigation, and control, the utilization of unmanned aerial vehicles (UAVs) has grown more widespread. This research paper conducts a comprehensive investigation into the technological advancements of robotic arms within the unmanned aerial vehicle (UAV) domain. By performing a comparative assessment across five distinct aspects - propulsion methods, structural configuration, control mechanisms, materials, and longevity, and usage scenarios - it delves into the strengths and weaknesses of both conventional and novel technologies, along with their prospective development paths. The research indicates that piezoelectric drive technology is capable of realizing lightweight robotic arms. For instance, there is a micro-aircraft whose total weight is merely 259 milligrams. Bionic flexible structures notably boost the adaptability to intricate environments. As an example, octopus tentacles can grasp an object with a diameter of 200 mm. The utilization of AI autonomous control and self-mending materials tackles the problems of poor precision in conventional remote control and restricted material longevity, respectively. Despite the fact that emerging technologies continue to face difficulties in terms of load-bearing capacity, cost, and the ability to adapt to extreme environments, their potential in new-age scenarios like healthcare services, forest surveillance, and deep-sea investigations has been verified. In the future, research efforts ought to combine multi-sensory perception, materials with variable stiffness, and standardized testing frameworks. This integration will propel the advancement of UAV robotic arms towards achieving greater intelligence and seamless integration across multiple scenarios.

Keywords: Robotic arms; unmanned aircraft; Industry 4.0; Emerging Fields

1. Introduction

Robotic manipulators find diverse applications in everyday life. In industrial fabrication, they are employed for the production of various goods, encompassing the manufacturing of automobiles and electronic devices. Beyond that, they can offer support in intricate real-life situations, for example, in warehouse logistics and the service sector. Furthermore, they possess considerable application prospects in vital domains such as resource prospecting and engineering building.

In the realm of human society, the adaptable utilization of robotic arms has substantially diminished both labor and material expenses. Concurrently, it has generated a multitude of novel employment prospects in technical domains. As the range of applications for robotic arms across diverse sectors keeps growing, the technological innovation associated with them has become progressively crucial and conspicuous. The persistent progress of robotic arm technology might gradually close the technological disparities demanded by the modern era, fulfill the application requirements of present-day mainstream robotic technology, and also uncover more potential for the future evolution of related technologies.

In the contemporary landscape, drones represent a widely debated application technology. Concurrently, a wide array of technologies that can be used in drones has attracted growing interest. The incorporation of robotic arms into the drone domain has become an essential element, and the technological advancements of these employed robotic arms have emerged as a crucial impetus for the advancement of future novel technologies. When it comes to innovation in drone technology, specific technical areas that merit attention encompass propulsion methods, architectural design, control mechanisms, and materials.

Determining how to evaluate the technological advancements of robotic arms within the drone industry, uncovering further latent possibilities, accurately examining the merits and demerits of such innovation, and integrating these positive and negative aspects with the actual requirements of background applications for reciprocal enhancement are all significant subjects that merit discussion and investigation. The purpose of this article is to conduct a study and draw conclusions regarding the technological innovations of robotic arms in crucial sectors, particularly in the realm of drones.

2. Comparison of Five Aspects of UAV Mechanical Arms

2.1 Comparison of Motor Drive and Piezoelectric Drive

The conventional driving approach for the robotic arm mounted on the unmanned aerial vehicle (UAV) is motor-powered operation. A prime example is the motor-driven compartment of the DJI FlyCart30. Based on the specifications from the official website, the main unit can weigh as much as 2.5 kilograms (not including the counterweight and hook). The substantial weight, which is a shortcoming of the traditional motor-driven system, restricts its ease of use.

Piezoelectric drive technology relies on the reverse piezoelectric effect of piezoelectric substances. When an electric field is applied, these substances can undergo mechanical deformation, thereby enabling motion output. Traditional drives are plagued by unfavorable scaling rules, such as the deterioration of electromagnetic motor performance and the rise in friction losses of conventional bearings. Piezoelectric substances can act as a driving force and present an ideal solution to these corresponding issues.

In the United States, a research team has developed a novel type of micro-aircraft powered by piezoelectric technology. The wings of this aircraft can be seen as a unique form of robotic arm, facilitating cable-free flight. Adopting this driving approach makes the entire product lightweight. The aircraft has a mass of 90 milligrams, and the overall system weighs 259 milligrams [1]. Additionally, it can fly using only 110 - 120 milliwatts of power, suggesting that its thrust efficiency is on par with that of similarly sized insects (like bees). Under specific conditions (193 V), this device achieved a lift - to - power ratio of around 2.4, whereas the lift - to - power ratio of the smallest quadcopter (such as the Aerix quadrotor) is 2.3. The device's mass and power consumption are approximately 1/25 of that [1]. The more lightweight design brings numerous benefits. For instance, in future experiments, it can obtain energy from photovoltaic cells and land on delicate surfaces [1]. At the same time, the lower mass implies less kinetic energy and reduced safety requirements for application settings. This improvement in size, weight, and power density is highly significant for enhancing the operational efficiency of unmanned aerial vehicles (UAVs) and broadening their application areas [1].

It is important to note that because of its low kinetic energy and associated size constraints, it may not be actively utilized in some industrial situations that demand suffi-

cient equipment kinetic energy. Nevertheless, in a wider range of application scenarios, it definitely opens up more opportunities. Based on piezoelectric drive technology, it might be suitable for more outdoor working environments.

2.2 Comparison of Traditional Rigid and Bionic Flexible Mechanical Arms

Conventional rigid robotic arms hold fundamental benefits, specifically substantial load - carrying capabilities and accurate motion regulation. Take the ABB industrial robot as a prominent instance. It has a carbon - fiber or metallic framework that can support loads reaching up to several tens of kilograms. This type of robot is commonly utilized in well - organized environments such as automobile assembly lines.

Nonetheless, rigid robotic arms depend on accurate environmental mapping. In unstructured surroundings, for example, rescue missions in debris or underwater investigations, they are likely to encounter malfunctions. This is because of the irregular forms of objects or the complex topographies in these areas. Additionally, rigid impacts can present safety hazards to both workers and machinery. To address these constraints, novel structural designs have been successfully put into practice. Bionic flexible robotic arms attain environmental adaptability by emulating biological forms, such as octopus tentacles and parrot feet. For example, the bionic soft water-based gripper intended for underwater operations consists of six hydraulically actuated soft tentacles. Each tentacle incorporates a suction cup and a gradually narrowing cavity structure. This enables it to grip a cylinder with a diameter of 200 mm and execute all-around crawling and three-dimensional swimming. Its pliable design allows for automatic adjustment to the shapes of objects, greatly improving operational proficiency in confined spaces or intricate terrains [2].

Moreover, the bionic habitat robotic arm adopts the inter-toe grasping technique of peacocks, making use of a modular rope-driven system. Weighing only 275 g in total, it enables an unmanned aerial vehicle (UAV) to firmly grasp a branch, thereby overcoming the endurance hurdle in forestry monitoring [3].

The soft materials employed in the adaptable robotic arm minimize the likelihood of collisions. This characteristic renders it well-suited for medical collaborative settings or human-machine integration situations. However, as indicated in reference [3], the load-carrying ability of this robotic arm is constrained by the strength of its materials. Consequently, it becomes arduous for the arm to substitute for heavy-duty industrial operations.

In order to delve deeper into the potential applications of flexible robotic arms, it is essential to integrate nonlinear

mechanical models with control logic optimized by AI algorithms. Take the bionic habitat robotic arm as an illustration. It employs the D-H parameter approach to formulate the kinematic equation of the claw. Subsequently, it validates the grasping trajectory via MATLAB random sampling simulation, and finally maintains stability at a 30° inclination [3].

Looking ahead, future research avenues involve the incorporation of variable-stiffness materials, like magnetorheological elastomers, to strike a balance between flexibility and load-bearing ability. Another direction is the integration of tactile sensors to improve the accuracy of environmental perception.

2.3 AI Autonomous and Manual Remote Control

Robotic arms that are manually operated via remote control rely on the operator's expertise and real-time input of commands. These robotic systems are particularly well-adapted for tasks with a high degree of uncertainty, like bomb defusing and emergency relief operations. Take bomb disposal drones as an example; they are remotely steered using a controller or a virtual reality device to relocate hazardous items.

Nonetheless, the precision of these remotely-controlled robotic arms can be affected by the operator's weariness and communication lags. This is especially true when satellite links are used for long-distance control. Moreover, their capacity to dynamically avoid obstacles is restricted. When confronted with the constraints of manually remotely - operated robotic arms, AI - autonomously - controlled robotic arms can potentially surmount these hurdles via their fundamental technologies. These AI - enabled robotic arms construct a "perception - decision - execution" feedback loop by utilizing algorithms.

Take an Industrial 4.0 warehouse as an illustration. Drones equipped with blockchain and RFID technology independently scan inventory tags along pre - determined routes. They are capable of completing item tracking for 13 items within 26 seconds and guarantee data integrity through Ethereum smart contracts [4]. The AI visual servo system is able to adjust the position of the robotic arm in real - time. It boasts a repetitive positioning precision at the micrometer scale, which substantially boosts the efficiency of precision manufacturing.

Edge computing technology decentralizes data processing. It minimizes communication latency to the millisecond range and enhances the robotic arm's capabilities in dynamic obstacle avoidance and real - time response [4].

However, AI models are dependent on a vast amount of pre-trained data. They have restricted generalization ca-

capacity in unfamiliar situations. To overcome the data-dependency bottleneck, small-sample learning needs to be incorporated [4].

Owing to this unpredictability, in certain conventional settings, AI-autonomously-controlled robotic arms may not be able to supplant the suitability of traditional remotely-operated robotic arms.

Numerous fundamental AI technologies within AI autonomous control enable the intelligent handling of robotic arms in industrial uses, and they play a role in enhancing precision and efficiency in industrial engineering. Sophisticated models such as GPT-4 streamline the programming of human-machine interaction directives. Operators are able to convey task objectives using everyday language, and AI then automatically creates control codes.

Looking ahead, the future direction of AI - autonomously - controlled robotic arms might focus more on the development of comprehensive intelligent systems. Constructing a multi-modal integrated control system that combines vision, force sensing, and voice interaction can result in “human-like” decision-making abilities.

2.4 Self-healing Materials Compared with Traditional Metal/Plastic

Conventionally, metallic and polymeric materials are widely employed due to their affordability and well-developed fabrication procedures. Take, for instance, the mechanical arm of the DJI Matrice 300, crafted from an aluminum alloy, which falls into this category of materials. However, these materials are comparatively hefty, with a weight exceeding 2 kg. This extra mass has an adverse effect on the drone’s flight endurance. Additionally, metals are liable to corrode, and plastics are prone to deterioration over time. As a result, their long-term application in marine or chemical settings is limited.

In response to more exacting environmental utilization requirements, the implementation of self-repairing materials in robotic arms has received greater attention. Self-repairing materials are capable of independently mending damage via molecular structure design. The SHUG gripper, developed by Delft University of Technology in the Netherlands, makes use of Diels-Alder reversible covalent bond polymers. At 70°C, it can seal scratches within 9 minutes, and macroscopic puncture damage can regain 90% of its mechanical properties after 4 hours of temperature-regulated sealing [5]. Its lightweight composite materials boost the drone’s payload efficiency. Moreover, the material’s resistance to acids, alkalis, and ultraviolet rays expands its usability in nuclear power plants or deep-sea exploration settings. Nevertheless, the development expense of self-repairing materials is substantial,

around three times that of conventional materials, and the high-temperature activation mechanism malfunctions in extremely cold conditions, which impedes the commercialization progress [5].

The SHUG gripper incorporates the design of filling with steel balls and optimizing the membrane thickness. By means of finite element analysis (FEA), it achieves a balance between thermal conductivity (50.2 W/(m·K)) and grasping force, with a peak grasping force reaching 11.5 N [5].

Looking ahead, it is crucial to devise self-healing mechanisms activated by light or chemicals to cut down on energy usage. Alternatively, it is worth exploring biodegradable materials for the purpose of environmental recycling.

2.5 Comparison between Emerging Fields and Traditional Industries

In conventional industrial settings, the primary requisites revolve around a high degree of precision and a high level of repeatability. Take, for instance, the KUKA industrial robotic arm, which is capable of achieving positioning accuracy at the millimeter scale during automotive welding processes. Nevertheless, this robotic arm is reliant on a well - structured environment and safety barriers. As a result, it faces challenges in adapting to tasks with dynamic requirements.

Within the realm of medicine, the Da Vinci surgical robot, when combined with a drone delivery system, is capable of conducting highly accurate micro - scale surgical procedures within a germ - free setting. This innovation not only marks a substantial boost in the efficiency and security of instrument transfer during surgical operations but also expands the possibilities for remote surgical interventions.

For intricate surgical procedures like multi - organ combined transplants, it furnishes unparalleled logistical assistance. Moreover, it holds the promise of enabling areas with limited medical resources to avail themselves of high - quality minimally invasive surgical services [6].

Within the realm of forestry surveillance, the biomimetic habitat robotic arm empowers drones to seize branches in a more productive manner. Owing to its lightweight construction and two - stage gripping system, it can stretch the operational period up to 4 hours. Its reliable performance on a 30° incline significantly boosts the long - term efficacy and the ability to adapt to intricate terrains for forestry resource assessments, pest and disease surveillance, and wildfire detection. This offers a low - energy, stable approach for forest ecological studies [3].

During marine exploration endeavors, soft grippers serve a dual purpose: they are capable of clearing underwater

waste and carefully holding archaeological relics. This functionality addresses the practical constraints of conventional rigid robotic arms. As a result, it substantially broadens the extent and range of human activities in three key areas in the deep - sea environment. These areas include environmental management, scientific research, and the safeguarding of cultural heritage.

In the realm of power maintenance, the AERIAL - CORE aerial operation robot system has the ability to independently install bird protection equipment and electrical insulators on high - voltage transmission lines. It achieves this via two distinct methods. The first is direct operation during flight, for example, it can perform a high - pressure push of bird spikes within 20 seconds. The second is human - machine collaborative operation, where a dual robotic arm platform mimics human dexterity to install spiral bird deterrents. This technological advancement eradicates the significant risks related to manual climbing. It also boosts the installation efficiency by a factor of three and saves more than \$10,000 per operation. Moreover, it presents the initial all - stack autonomous operation model that combines insulation protection, precise operation, and energy management for high - altitude and high - risk situations such as those found in power grids and bridges. This represents a substantial breakthrough in the intelligent maintenance of infrastructure [7].

When it comes to disaster response, the fully-driven hexacopter aerial mechanical hand system conducts infrastructure detection based on contact through the combined use of multiple technologies. The fully-driven hexacopter platform can autonomously regulate its attitude and position. It can precisely hover in restricted spaces such as under bridges or inside tunnels while exerting horizontal forces. At the same time, the spring-electrode force sensor at the end of the lightweight 3 - degree - of - freedom mechanical arm provides real-time feedback on the contact pressure. This enables closed-loop force control for ultrasonic detection or sensor installation. For instance, it can simulate the need to maintain a 10N pressure when using adhesive sensors. This system replaces high-risk human operations and realizes automated contact-based detection. It overcomes the drawback of traditional unmanned aircraft, which can only observe but not make contact. This indicates the evolution of infrastructure maintenance towards “precision operation-level” unmanned aircraft technology [8].

Within the domain of wind turbine visual assessment, the self-operating unmanned aerial vehicle system conducts visual examinations of wind turbines via the coordinated operation of three fundamental technologies. For the very first time, it has proven the viability of fully self-directed

and multi-unmanned aircraft cooperative detection within an actual wind power plant. The modular configuration surmounts the positioning and perception limitations encountered in the inspection of large-scale, featureless infrastructure. As a result, it offers a reusable technological blueprint for automated inspections in the energy and infrastructure industries [9].

Furthermore, during space exploration endeavors, robotic arms must endure high-intensity radiation and the harsh conditions of a vacuum. In this context, self-healing materials and smart driving technologies are likely to emerge as crucial enabling technologies.

The application prerequisites of cutting-edge fields offer an epochal chance for advancements and breakthroughs across multiple facets of novel robotic arms. Simultaneously, they bring about more creative challenges. To illustrate, innovations in materials, such as the corrosion-resistant coating with a bionic shell configuration, and multi-modal sensing technologies, like the fusion of LiDAR and infrared, are propelling robotic arms towards integration across diverse scenarios. Looking ahead, it is essential to set up a standardized testing framework to validate the reliability of these robotic arms in harsh conditions. Additionally, exploring modular design approaches can enable rapid adaptation to different task specifications. Despite the remarkable achievements in robotic arm technology within the research realm, numerous obstacles remain on the journey from the laboratory to the commercial market. As per insights from relevant authorities, the principal technological hurdles in the current Chinese context encompass high-accuracy modeling, real-time regulation, and the refinement of intelligent algorithms. Moreover, during the industrialization phase, concerns such as manufacturing expenses, market compatibility, and supply-chain backing must be tackled [10].

In a broader spectrum of domains, there is an imperative for innovative advancements. Integrating more cutting-edge technologies into the mechanical arms of unmanned aerial vehicles can broaden their prospective application scenarios in the future.

3. Conclusion

The technological breakthroughs of robotic arms within the domain of unmanned aerial vehicles (UAVs) are steadily surpassing the limits of conventional industrial uses. These primary developments are manifested in five different areas.

When it comes to the driving approach, piezoelectric drive technology presents novel ways to boost the endurance and broaden the usage scenarios of unmanned aerial vehi-

cles (UAVs) due to its lightweight construction and high energy utilization. Nevertheless, it has to overcome the drawback of inadequate kinetic energy for heavy - industrial use cases.

Regarding the structural layout, bionic flexible robotic arms display notable benefits in unstructured settings. However, their load - carrying capacity needs to be further refined by employing variable - stiffness materials.

In the control scheme, the integration of artificial intelligence (AI) autonomous control with edge computing technology and natural language programming considerably enhances task effectiveness. Still, in unfamiliar situations, incorporating small - sample learning is essential to improve the generalization capacity.

In relation to materials and longevity, self - healing materials increase the usability in extreme conditions through self - repair of damages. Yet, high expenses and triggering mechanisms slow down their commercialization progress.

In application areas, emerging sectors require robotic arms to have better lightweight design, corrosion resistance, and multi - modal perception capabilities. As a result, there is an urgent need for modular design and standardized testing systems.

Subsequent research ought to center on the amalgamation of cross - disciplinary technologies. Take, for instance, the combination of biomimicry and artificial intelligence algorithms, which can refine control logic. Alternatively, the creation of light or chemical - triggered self - repair mechanisms can cut down on energy usage. At the same time, it is of great significance to expedite technology dissemination through cooperation among industries, universities, and research institutions. This will help facilitate the widespread implementation of unmanned aerial vehicle (UAV) robotic arms in sectors like Industry 4.0 and smart cities. Ultimately, this will lead to the attainment of the comprehensive technical objective of “efficiency - safety - sustainability”.
